Response of Italian Ryegrass to Crop Rotation and Indaziflam in Eastern Washington

Lyman, K.C. and I.C. Burke

Italian ryegrass is becoming more prevalent and widespread within eastern Washington, with higher rates of resistance to numerous herbicide modes of action. Knowledge of the effects of management inputs on the seed bank of Italian ryegrass is critical component of an integrated management system. However, little is known of the impact of herbicide input or crop rotation on Italian ryegrass seedbank in Washington. The objectives of the study were to evaluate the effect of crop rotation and associated herbicide inputs on the Italian ryegrass seedbank, as well as evaluate the impact of indaziflam, very long lived soil residual herbicide, for management of Italian ryegrass. The preemergence herbicide indaziflam was used to prevent the germination of Italian ryegrass seedlings at the WSU Cook Agronomy farm, near Pullman WA. and near Almota, WA.

A study with two trials were established at the WSU Cook Agronomy farm near Pullman and the second trial near Almota, WA in the spring of 2020. The study was conducted as a randomized complete design with three main plot treatments and four replications. Plots were 30 ft wide by 35 ft long. Soil seedbank samples were collected from the trial site before planting and after harvest each year. A Wintersteiger or Kinkaid plot combine with a 5-ft header was used to harvest plots. All treatments were applied using a CO2 powered backpack sprayer calibrated to 15 gallons per acre, at 3 mph. In year 1, indaziflam was applied postemergence to soft white spring wheat. For both trials, indaziflam treatments were applied with Axial Bold and NIS on May 8th of 2020 at the 2 to 3 tiller stage of the spring wheat (Table 1). Italian ryegrass had already emerged. Percent spring wheat injury assessments occurred 1 month after treatment and Italian ryegrass density was assessed for both trials 1 month after treatment and before harvest from 2 1-m² quadrats placed randomly in each plot (Tables 2 and 3). Harvest at the WSU Cook Agronomy study began on September 3, 2020 and harvest began on August 27, 2020 at Almota. For the second cropping year, dryland rotational small grain and broadleaf crops were planted to assess effects of crop rotation and the preemergence application of indaziflam applied the previous season. Each main plot was divided into 5 sub plots, measuring approximately 7 feet wide and 35 feet long. Soil seedbank samples were collected from the main plots before planting and from each sub-plot after harvest for analysis of the Italian ryegrass seedbank. Weekly assessments of percent crop injury for winter wheat, canola, barley, chickpea, or fallow were recorded for each site location (Table 2). Italian ryegrass density was assessed with 2 1-m² quadrats place randomly in each sub-plot at planting and before harvest (Table 3). For the third cropping year, winter wheat was planted at both locations to further access the effects from the preemergence application of indaziflam applied two seasons previously. Winter wheat was established across the main plots as in year 1, measuring approximately 35 feet wide by 30 feet long. The impact of indaziflam treatments applied in year 1 as well as the year 2 annual dryland rotational crops were assessed. Unfortunately, winter wheat failed to emerge in Pullman, and was replanted to spring wheat in the spring of 2022. At the Almota site, spring assessments of percent crop injury were recorded 23.5 months after indaziflam treatment during the critical growing stages for winter wheat (Table 2). At the Cook Agronomy site, spring visual assessments of percentage crop injury 25 months after indaziflam treatment (Table 2). At both site locations, Italian ryegrass density was recorded approximately 19 months after indaziflam treatment and...
before year 3 harvest on a per-plot basis, using 2 1-m² quadrats placed randomly in each sub-plot. Density was averaged across quadrats prior to analysis (Table 3). At the Almota site, harvest occurred on August 30, 2022 for winter wheat. At the Cook Agronomy site, harvest occurred on September 13, 2022 for spring wheat. Final soil seedbank samples were collected post-harvest after the third and final harvest. Soil elutriation occurred after all seedbank samples were gathered and thawed (Table 5). Year 1, 2 and 3 data were analyzed separately using ANOVA with Proc GLIMMX and Proc mixed in SAS (SAS Institute 2022). The LS-means argument was added to the SAS code to generate estimates for means of treatments and to compare all treatments against each other with $\alpha \leq 0.05$.

Yields of the spring wheat crop in 2020 were not impacted by the application of indaziflam, indicating crop safety when applied postemergence in spring wheat. In 2021, yields were variable in Almota and very low in Pullman due to drought. Chickpea yield was not affected by treatment with indaziflam the previous season, but winter wheat, barley and canola yields were reduced. At both locations, Italian ryegrass density decreased with increasing rates of indaziflam, with canola and fallow achieving nearly complete control of Italian ryegrass seed production in year 2. Barley, chickpea, and winter wheat rotations showed increasing Italian ryegrass control with the increasing rates of indaziflam.

In 2022, a weakly significant response to indaziflam was observed in winter wheat that did not translate to significant impact to yield at Almota, likewise for the spring wheat yield at Pullman. The various crop rotations had no impact on year 3 winter wheat and spring wheat yield. Italian ryegrass control increased with increasing rates of indaziflam, though the impact on seed density was less pronounced. Final seed bank density in the indaziflam-treated plots were either the same or lower than the standard production practice treated plots but varied by location and the crop rotation from the previous year. In general, chickpea rotations combined with high rates of indaziflam appeared to have the largest impact on decreasing the seedbank density. Indaziflam appears a potential candidate for use as part of an integrated Italian ryegrass management system in dryland wheat production, particularly when rotations include chickpea.
Table 1. Crop rotations and crop management inputs as in year 1, 2 and 3 for trials located in Almota and Pullman, WA.

a Initial broadcast application of pyroxasulfone applied at 1.20 g ai ha⁻¹ and glyphosate applied at 950 g ai ha⁻¹ prior to all fall planting events and for 2020, 2021 and 2022 trial years.
b Initial broadcast application of glyphosate applied at 950 g ai ha⁻¹ prior to all spring planting events for 2020, 2021 and 2022 trial years.
c All broadcast sprayer treatments were applied with Induce, nonionic surfactant at 0.25% on a volume product per volume mix basis.
d First and second listed dates within each trial year were applied in Almota and Pullman, respectively.
e Year 3 at Pullman, spring wheat consisted of a Goldsky application at 117 g ai ha⁻¹ instead of Talinor and Axial XL.
